ABSTRACT

Background: We aimed to evaluate the morphology of maxilla and sinus dimensions in subjects with unilaterally and bilaterally impacted canine using cone beam computed tomography (CBCT) records.

Methods: CBCT records taken during 2020-2022 of 120 patients were obtained to investigate the relationship between impacted canine and maxillary morphology as well as sinus dimensions. The CBCT images were then divided into three groups: control, unilaterally canine impaction and bilaterally canine impaction. Then morphology-related variables (arch circumference, arch length, inter molar width, inter first premolar width, palatal depth, anterior posterior dimension of the right and left sinuses, and mediolateral dimension of the right and left sinuses) were analyzed and compared between groups. All measurements were done by Ondeman 3D dental software. Statistical analysis was carried out by SPSS software version 21 using one-way ANOVA.

Results: There were meaningful differences in patients with canine impaction compared with control group in arch circumference (P value= 0.004) and arch length (P value= 0.001), inter molar width (P value= 0.001), inter first premolar width (P value= 0.001), mediolateral dimension of the right (P value=0.001) and left (P value= 0.001) sinuses of maxilla. Furthermore, Palatal depth and anterior posterior dimension of the right and left sinuses did not show statistically significant difference between groups.

Conclusion: Canine impaction can considerably affect the morphology of maxillary and sinuses dimensions. Nevertheless, future studies are needed to determine the exact structural and molecular effects of the canine impaction on maxillary sinuses and neighboring tissues.

INTRODUCTION

Impaction of permanent maxillary canine is a common problem in orthodontics. After third molar teeth, maxillary canine teeth are highly prone to be impacted, with an incidence rate of 1.1-13%¹⁻³. Impacted

teeth are referred to teeth that are not able to complete their eruption process in a timely manner⁴. Clinicians have different definitions regarding the term impaction⁵⁻⁹.

More exactly, from pathological perspectives, impacted teeth are remained embedded in oral mucosa or bone after their normal time of eruption. However, clinical definition of impaction is related to teeth that undergo ectopic eruption or teeth that induce root resorption of adjacent teeth, even before the normal eruption time span. The position of an impacted canine can be on palatal, labial or intra-alveolar sides, of which palatal location has the highest degree of prevalence^{10,11}.

The etiology of canine impaction still remains controversial. However, it has been suggested that local pathology, local hard tissue obstruction, departure from or disturbance of the normal development of the incisors, and genetic factors can be considered as the main causes of maxillary canine impaction¹².

The impacted maxillary canine is capable of disturbing adjacent teeth alignment, reducing dental arch length, inducing ankylosis, increasing dentigerous cyst formation and causing recurrent infections¹³. The maxillary canine impaction can affect the morphology of maxillary sinus, which is a bilateral air-filled chamber in the maxilla and the largest paranasal sinus¹⁴⁻¹⁶. More precisely, extraction of premolar and canines can lead to sinus pneumatization and/or expansion, mainly due to proximity of these teeth to maxillary sinuses¹⁷.

After clinical examination, orthodontists apply radiography in order to recognize the location of maxillary canine impaction¹⁸. In this regard, panoramic radiograph determines the existence of an impacted canine. However, three-dimensional (3D) cone-beam computed tomography (CBCT) can detect the exact location of the canine impaction^{19, 20}. In addition, CBCT can help predict the link between the impacted canine and its surrounding teeth and other anatomical structures as well as identifying possible resorptions¹⁸.

Data on the effect of maxillary canine impaction on the morphology of maxilla have been revealed to be different among patients and thus are inconsistent. It is also important to note that, hitherto, there has been no study investigating simultaneous effect of maxillary canine impaction on the morphology of maxilla and dimensions of maxillary sinus.

Therefore, we aimed to Evaluate the relationship between maxillary canine impaction with arch dimensions and maxillary sinus dimensions using Cone Beam Computed Tomography (CBCT).

MATERIALS AND METHODS

Samples

CBCT recordings taken during 2020-2022, were collected from Radiology archive of the Hamadan University of Medical Sciences, Hamadan, Iran. These CBCT recordings have been provided with the use of CBCT instrument (Newtom 3G, Verona, Italy, Fov=12 inch, kVp=110, mA=1.6). A total of 120 CBCT scans were selected based on inclusion and exclusion criteria. The inclusion criteria included:

- 1) Canine has not erupted after more than one year since the eruption of the upper first and second molars (only for the group with unilateral and bilateral impaction)
- 2) CBCT radiographs should represent the whole maxillary arch
- 3) The patient must be at least 15 and at last 35 years old.

The exclusion criteria were as follows:

- 1) Patients with cysts, tumors, dental trauma or any lesions that may have obstructed canine growth
- 2) Patients with skeletal anomalies or systemic diseases
- 3) Patients with craniofacial anomalies
- 4) Patients with a history of undergoing orthodontic appliance or dental surgeries
- 5) Patients who have lost their teeth (except for central incisor).

Collected CBCT scans were divided into control (n = 40), unilateral palatal impacted canine (n = 40) and bilateral palatal impacted canine (n = 40) groups. Then nine variables including arch circumference and arch length, inter molar width, inter first premolar width, palatal depth, anterior posterior dimension of right and left sinus, and mediolateral dimension of right and left sinus were compared among three groups. Furthermore, all measurements are measured by Ondeman 3D dental software (Cybermed, Seoul, Korea), the unit of measurement is millimeter.

The variables were measured in the following way:

Arch circumference: In the axial view, from the mesial contact point of first molar on the arch to the mesial contact point of first molar on the opposite

Inter first premolar width: In the axial view, transversely from the buccal cusp of the first premolar to the buccal cusp of the first premolar on the opposite side (Figure 1)

Arch length: In axial view, longitudinally from the contact point of the centrals to the line that defines the inter molar width (Figure 1)

extended from the tip of the mesiopalatal cusp of first molar on one side to the mesiopalatal cusp of first molar on the opposite side. It was measured from the deepest point of the palate to the connecting line of the cusps (Figure 2)

Ethical statement: This study was reviewed and approved by the ethics committee of Hamadan University of Medical Sciences (IR.UMSHA.REC.1399.588).

Statistical analysis

Statistical analysis was carried out by SPSS software version 21 (IBM Corp., Armonk, NY, USA) using one-way ANOVA. All data were expressed as mean \pm SD. *P* values less than 0.05 were considered as statistically significant.

RESULTS

Descriptive analysis of all study groups has been summarized in Table 1.

Moreover, comparison analysis between study variables have been represented in Table 2. The information provided in this table indicate that both arch circumference and arch length, inter molar width and inter first premolar width were remarkably different between unilaterally and bilaterally canine impaction groups. Comparison between bilaterally impacted canine and control subjects showed statistically significant results for arch length, intermolar width and inter first

premolar width variables. Among these variables, inter first premolar width was revealed to be notably different between unilaterally canine impaction and control groups ($P < 0.004$). In addition, palatal depth and anterior posterior of right side sinus showed no significant difference in all studied groups. Paired comparison between all groups revealed that mediolateral dimension of right and left side sinuses are remarkably different between unilateral impacted canine and control as well as bilateral impacted canine and control groups.

DISCUSSION

This study was designed to determine the relationship between maxillary impacted canine with the width and depth of the palate and maxillary sinus dimensions using cone beam computed tomography.

Over the past years, CBCT has gained importance as a reliable diagnostic method, due to its high level

of precision in angular and linear measurements ²¹. Lateral cephalometric radiographs pose many disadvantages, of which it can be mentioned that images driven from these radiographs might be different from the actual size. Moreover, neighboring structures superimpose boundaries of the maxillary sinus, which is specially occurred in the deeper areas of nasomaxillary complex ²².

Intriguingly, CBCT represents more accurate measurement of maxillary sinus volume with smaller radiation doses and lower cost than computed tomography magnetic resonance imaging technique ²³. Hence, CBCT recordings were used in this study to evaluate the relationship between canine impaction and maxillary sinus morphology. In the present study, arch circumference and arch length, inter molar width, inter first premolar width, mediolateral dimension of right and left side sinuses, were significantly different in unilateral and bilateral samples with canine impaction as well as control group. These findings indicate that canine impaction and its location can have a remarkable effect on the morphology of maxilla. Our results further support the idea of Kim et al. who demonstrated that in patients with palatally impacted canine, the palatal vault is deep and the shape of maxillary arch is narrow and long ²⁴. Findings of this study are also in consistent with previous studies, which reported that canine impaction affects the volume of maxillary sinus ^{14, 25}.

Another important finding was that the arch circumference and intermolar width of maxilla are significantly different between patients with unilaterally and bilaterally impacted canine. In accordance with these results, arch circumference was wider in the impaction side ²⁶. also, another study showed decreased intermolar width and arch circumference in impacted maxillary canine ²⁷. Herein, both arch circumference and intermolar of maxilla were found to be remarkably different between bilaterally impacted canine and control groups. However, we observed no statistically significant difference between unilateral impacted canine samples and control group. Thus, it can be interpreted that bilaterally impacted canine might have stronger impacts on the maxillary sinus. Moreover, we found that mediolateral dimension of right and left sides of sinus in unilaterally and bilaterally impacted canines are significantly different as compared with control samples.

One of our interesting findings was significant changes of inter first premolar width among all groups, indicating that either unilateral or bilateral canine impaction can considerably affect this variable in the maxilla.

In this study, arch circumference in unilateral canine impaction samples were significantly different from control group, which means that for these particular variables, the side of canine impaction can be determinant factor contributing to changes in maxillary morphology.

CONCLUSION

Returning to the hypothesis posed at the beginning of the present study, it is now possible to state that canine impaction can structurally and morphologically impact surrounding maxilla. Impacted canine can alter arch circumference and arch length, inter molar width and mediolateral dimension of maxillary sinus. However, future studies are needed to determine the exact structural and molecular effects of the canine impaction on maxillary sinuses and neighboring tissues.
